Abstract

Parallel TCP flows are broadly used in the high performance distributed computing community to enhance network throughput, particularly for large data transfers. Previous research has studied the mechanism by which parallel TCP improves aggregate throughput, but there doesn't exist any practical mechanism to predict its throughput and its impact on the background traffic. In this work, we address how to predict parallel TCP throughput as a function of the number of flows, as well as how to predict the corresponding impact on cross traffic. To the best of our knowledge, we are the first to answer the following question on behalf of a user: what number of parallel flows will give the highest throughput with less than a p % impact on cross traffic? We term this the maximum nondisruptive throughput. We begin by studying the behavior of parallel TCP in simulation to help derive a model for predicting parallel TCP throughput and its impact on cross traffic. Combining this model with some previous findings we derive a simple, yet effective, online advisor. We evaluate our advisor through extensive simulations and wide-area experimentation.

1. Introduction

Data intensive computing applications require efficient management and transfer of terabytes of data over wide area networks. For example, the Large Hadron Collider (LHC) at the European physics center CERN is predicted to generate several petabytes of raw and derived data per year for approximately 15 years starting from 2005 [5]. Data grids aim to provide the essential infrastructure and services for these applications, and a reliable, high-speed data transfer service is a fundamental and critical component.

Effort sponsored by the National Science Foundation under Grants ANI-0093221, ACI-0112891, ANI-0301108, EIA-0130869, and EIA-0224449. Any opinions, findings and conclusions or recommendations expressed in this material are those of the author and do not necessarily reflect the views of the National Science Foundation (NSF).

Recent research has demonstrated that the actual TCP throughput achieved by applications is, persistently, significantly smaller than the physical bandwidth “available” according to the end-to-end structural and load characteristics of the network [30]. Here, we define *TCP throughput* as the ratio of effective data over its transfer time, also called *goodput* [27].

Parallel TCP flows have been widely used to increase throughput. For example, GridFTP [4], part of the Globus project [10], supports parallel data transfer and has been widely used in computational grids [5].

A key challenge in using parallel TCP is determining the number of flows to use for a particular transfer. This number affects both the throughput that the transfer will achieve and the impact that it will have on other traffic sharing links with these data flows. While there has been significant previous work on the understanding of parallel TCP performance, no practical parallel TCP throughput prediction techniques exist and there is no analysis work or system that can support the following API call:

```
struct ParallelTCPChar {
    int    num_flows;
    double max_nondisruptive_thru;
    double cross_traffic_impact;
};
ParallelTCPChar *
TameParallelTCP(Address dest,
                 double maximpact);
```

Here, the user calls `TameParallelTCP()` with the destination of her transfer and the maximum percentage impact she is willing to have on cross traffic. The call evaluates the path and returns the number of parallel flows she should use to achieve the maximum possible throughput, while causing no more impact than the specified. We refer to this as the *maximum nondisruptive throughput (MNT)*.

The following sections address the implementation of such a function. With this in mind, we look for answers to the following questions:

- How does parallel TCP affect the throughput of the user's transfer, the throughput of cross traffic, and the aggregate throughput, in different scenarios?

- How can these throughputs be predicted, online and with a small set of measurements, as functions of the number of parallel TCP flows?
- How can these predictions be used to implement the `TameParallelTCP()` function?

To the best of our knowledge, we are the first to propose a practical mechanism to predict the throughput of parallel TCP flows and to answer `TameParallelTCP()`-like questions by estimating the impact on the cross traffic.

Throughout the paper, we use “parallelism level” interchangeably with “the number of parallel TCP flows”. A version of our `TameParallelTCP()` implementation is available from

<http://plab.cs.northwestern.edu/Clairvoyance/Tame.html>

2. Related work

The available bandwidth of a path is defined as “the maximum rate that the path can provide to a flow, without reducing the rate of the rest of the traffic.” [15, 16]. Available bandwidth has been a central topic of research in packet networks over the years. To measure it accurately, quickly, and non-intrusively, researchers have developed a variety of algorithms and systems. Tools that measure either the bottleneck link capacity or the available bandwidth include IGI [15], Remos [18], Nettekimer [17] and pathload [16], among others. Most of these tools use packet pair or packet train techniques to conduct the measurements and typically take a long time to converge.

Previous research [17] has shown that, in most cases, the throughput that TCP achieves is considerably lower than the available bandwidth. Parallel TCP is one response to this observation. Sivakumar et al. [30] present Pockets, a library that stripes data over several sockets and evaluate its performance through wide-area experimentation. The authors concluded that this approach can enhance TCP throughput and, in certain situations, be more effective than tuning the TCP window size. Allcock et al. [5] evaluate the performance of parallel GridFTP data transfers on the wide-area, and applied GridFTP to the data management and transfer service in Grid environments.

Considerable effort has been spent on understanding the aggregate behavior of parallel TCP flows on wide area networks. Shenker et al [29] were first to point out that a small number of TCP connections with the same RTT and bottleneck can get their congestion window synchronized. Qiu et al. [27] studied the aggregate TCP throughput, goodput and loss probability on a bottleneck link via extensive ns2-based simulations. They found that a large number of TCP flows with the same round trip time (RTT) can also become synchronized on the bottleneck link when the average size of each TCP congestion window is larger than three packets.

A detailed explanation for this synchronization was given in [27]. Due to global synchronization, all the flows share the resource fairly: in the steady state they experience the same loss rate, RTT and thus the same bandwidth.

The work most relevant to ours is that of Hacker et al [12]. The authors observe that parallel TCP increases aggregate throughput by recovering faster from a loss event when the network is not congested. The authors go on to propose a theoretical model for the upper bound of parallel TCP throughput for an uncongested path. The model produces a tight upper bound only if the network is not congested before and after adding the parallel TCP flows; the aggregated throughput then increases linearly with the number of parallel TCP flows. Clearly this reduces the utility of the model as networks are often congested.

Hacker et al also concluded that, in the absence of congestion, the use of parallel TCP flows is equivalent to using a large MSS on a single flow, with the added benefit of reducing the negative effects of random packet loss. They advise application developers not to use an arbitrary large number of parallel TCP flows, but conclude that it is difficult, if not impossible, to determine the point of congestion in the end-to-end path a priori, and therefore to decide on the proper number of parallel TCP flows.

Most TCP throughput models have limited practical utility due to the difficulty of obtaining accurate model parameters such as TCP loss rate and *RTT*. For example, Goyal et al [11] concluded that it is hard to obtain accurate estimates of network loss rates as observed by TCP flows using probing methods, and that polling SNMP MIBs on the routers can do much better. However, the MIB statistics are for the aggregate traffic crossing a interface on the router while it is well-known that TCP has a bias against long round trip time connections [27]; the approach is thus limited to those paths where the bottleneck router is using RED. It is also necessary in this and similar approaches to determine the bottleneck router on the end-to-end path (a difficult problem) and have SNMP access to it (rarely available today). Even if this is possible, with current models for parallel TCP we would have to know the loss rate *after* adding in n parallel TCP flows. However, even with the tools like web100 [21], we cannot obtain this rate by simply measuring the network.

Our work makes the following new contributions to the state of the art:

- We predict throughput for *both* congested and uncongested paths as a function of the level of parallelism.
- We estimate the impact of parallel TCP on cross traffic as a function of the level of parallelism.
- We do so using only a small number of probes and no additional tools.

It is widely believed that, under congested situations, parallel TCP flows achieve better performance by effec-

Figure 1. Simulation Topology.

tively behaving unfairly, stealing bandwidth from cross traffic. This has prompted some researchers to propose modifying TCP in order to make it better suited for parallel transfers by considering both efficiency and fairness [13, 14]. We believe it will be difficult to persuade people to modify their TCP implementations just to use parallel TCP more fairly. By relying on our prediction tools, a user or administrator should be able to trade off a transfer’s throughput and its degree of impact on cross traffic, achieving what we refer to as the *maximum nondisruptive throughput (MNT)*. All these are at application level without requiring modifications to pre-existing TCP implementations.

3. Analyzing parallel TCP throughput

In this section, we use simulation to understand the behavior of parallel TCP under different scenarios. For all our simulation-based studies we make use of the ns2 network simulator [2].

3.1. Simulation Setup

In a simulation study on aggregate TCP throughput on a bottleneck link, Qiu et al. [27] developed a simple yet realistic topology model for wide-area Internet connections based on the Internet hierarchical routing structure (Figure 1). We adopt this same topology for our simulations. Each simulation is 100 seconds long, with cross traffic randomly starting during the first 8 seconds and parallel TCP flows all starting at 10 seconds into the simulation. Cross traffic goes from N1 to N5, while parallel TCP flows go from N2 to N6. The bottleneck link is L3. We employ TCP Reno [8] for both cross traffic and parallel TCP flows, as this is the most widely deployed TCP congestion control algorithm. In addition, comparable results were obtained using TCP Tahoe. Both DropTail and Random Early Detection (RED) [9] queue management policies are studied as they are the most commonly used queue management policies on the Internet. DropTail and RED have similar performance in most our simulations. The exception is in Scenario 1. Here, when there are more than 10 cross traffic flows, the cross traffic dominates the queue and starves the parallel TCP flows under the DropTail policy. Unless otherwise noted, we show results for the DropTail policy.

Scenario	L ₃ Latency	L ₃ Bandwidth	L ₁ , L ₂ Bandwidth	L ₄ , L ₅ Bandwidth	TCP Buffer
1	20 ms	1.5 Mbps	10 Mbps	10 Mbps	$\geq BW * RTT$
2	20 ms	100 Mbps	1000 Mbps	1000 Mbps	$\geq BW * RTT$
3	50 ms	100 Mbps	1000 Mbps	1000 Mbps	$\geq BW * RTT$
4	50 ms	1000 Mbps	10000 Mbps	10000 Mbps	$\geq BW * RTT$
5	50 ms	1000 Mbps	10000 Mbps	10000 Mbps	60 KB
6	20 ms	100 Mbps	1000 Mbps	1000 Mbps	60 KB

The latency for L1 and L2 is fixed at 4 milliseconds, while the latency for L4 and L5 is fixed at 5 milliseconds. The buffer size on each node is fixed at 25 packets. Both DropTail and RED queue management policies are simulated.

Figure 2. Simulation Scenarios.

We use TCP flows as cross traffic because of TCP’s dominance in the current Internet, as reported in the the work by Smith et al. [31], in which TCP accounted for 90-91% of the packets and about 90-96% of the bytes transferred in traces collected in 1999-2000 from a educational institution (UNC) and a research lab (NLANR).

We analyze Parallel TCP throughput under a variety of representative scenarios including a typical slow connection such as cable or DSL (Scenario 1), a coast-to-coast high-speed Internet connection (Scenario 2) and a current (Scenario 3) and next generation global-scale Internet connections (Scenario 4). Two additional scenarios (Scenarios 5 and 6) are used to represent cases where the TCP buffer has not been appropriately tuned [32]. Figure 2 summarizes the different simulation scenarios. For each scenario, we simulate from 1 to 31 parallel TCP flows with 5, 10, 15, 20, 25 and 30 random TCP cross traffic flows.

3.2. Simulation results

We summarize our results in this section. Much more detail is available in our technical report [19].

Scenario 1 is used to represent a typical slow connection. Our simulations show that that the primary benefit from parallel TCP comes from being able to steal bandwidth from the existing cross traffic.

Scenario 2 represents a current coast-to-coast connection with low latency and medium bandwidth. Our simulations show that there are some limited benefits from using parallel TCP without competition in this scenario. In the presence of cross traffic, however, parallel TCP is an even stronger competitor. Parallel TCP allows us to increase overall throughput, albeit marginally.

Scenario 3 is a high latency, medium bandwidth link representing a current global-scale fast Internet connection. In this case there are significant benefits to using parallel TCP even in the absence of cross traffic. The performance of parallel TCP under scenarios 2 and 3, without cross traffic, can be explained using Hacker’s theory [12] that parallel TCP recovers faster than single TCP when there is a time out. This effect is more important as the RTT increases, because

the time out will be longer and a single TCP cannot recover fast enough.

The benefit of using parallel TCP, with and without cross traffic, are quite high in Scenario 4. Additional throughput in the presence of cross traffic, is mainly due to an increase in overall throughput.

The advantage of parallel TCP is even more significant with mistuned TCP buffers. Scenario 5 represents a high bandwidth and high latency link with a small socket buffer size. The benefits of parallel TCP are quite high, regardless of the amount of cross traffic. These gains come at no cost to the existing cross traffic. Parallel TCP gains performance not only by recovering faster after a time out, but also by providing an effectively larger buffer size. There are diminishing returns as the number of flows is increased. Scenario 6 is similar.

3.3. Observations

The dramatically different behaviors of the previous section illustrate the challenges in providing a sound `TameParallelTCP()`-like call. Parallel TCP and cross traffic as functions of the number of flows adopt a wide range of forms, depending on the topology of the network and the configuration of endpoints. In addition, even if one were to disregard the almost prohibitively high costs of directly measuring these curves, the cross traffic impact would be very difficult to determine. Without a priori knowledge of the parallel TCP loss rate, the model proposed by Hacker, et al [12] only works in uncongested networks like our Scenario 5.

4. Modeling and predicting throughput

In this section we combine our simulation work with our analytic treatment of TCP performance to develop a model that can be used to predict the throughput of parallel TCP flows in practice. Our approach only needs to send two probes at different parallelism levels and record their throughput. We don't need any additional tools to measure the *RTT* and loss rate, which can be hard to obtain in practice as we discussed in Section 1.

4.1. Algorithm

Mathis et al. [22] developed a simple model for single flow TCP Reno throughput on the assumption that TCP's performance is determined by the congestion avoidance algorithm and that retransmission timeouts are avoided:

$$BW = \frac{MSS}{RTT \sqrt{\frac{2bp}{3}}} \quad (1)$$

Here, p is the loss rate or loss probability, and b is the number of packets that are acknowledged by a received message. *MSS* and *RTT* are the maximum segment size and round trip time respectively.

Padhye et al. [26] developed an improved single flow TCP Reno throughput model that considers timeout effects.

Bollinger et al [7] show that these two models are essentially equivalent with packet loss rates less than 1/100, which was validated on the current Internet by Zhang et al [34]. Hacker et al. [12], based on Bollinger's findings, present a model for the upper bound of the throughput of n parallel TCP flows. The authors assume that both *MSS* and *RTT* are stable. Hacker's upper bound model can be stated as:

$$BW_n \leq \frac{MSS}{RTT} \left(\frac{1}{\sqrt{p_1}} + \frac{1}{\sqrt{p_2}} + \dots + \frac{1}{\sqrt{p_n}} \right) \quad (2)$$

where p_i is the packet loss rate for flow i . However, the authors don't provide any mechanism to estimate the loss rate at other parallel levels for prediction purposes. Therefore, the authors acknowledge that the upper bound is tight only when the network is not congested and the loss rate doesn't increase with more parallel TCP flows. The model only has limited utility otherwise.

In our model, we introduce the notion of the number of cross traffic flows, m , and assume that m does not change dramatically over significantly large time periods. Note that our model doesn't require knowledge of m . Both previous work [35] and our own work on characterizing, modeling, and predicting single flow TCP throughput [20] have shown this assumption to be a valid one.

It is widely believed that the TCP throughput shows statistical stability over considerable periods of time. Balakrishnan et al found that end-to-end TCP throughput to hosts often varied by less than a factor of two over timescales on the order of many tens of minutes, and that the throughput was piecewise stationary over timescales of similar magnitude [6]. Myers et al examined performance from a wide range of clients to a wide range of servers and found that bandwidth to the servers and server rankings from the point of view of a client were remarkably stable over time [25]. Zhang et al [35] used the notion of the Operational Constancy Region (OCR) to evaluate the temporal locality of end-to-end TCP throughput. The OCR is the length of the period where the ratio between the maximum and minimum observed TCP throughput is less than a constant factor ρ . They found that $\approx 60\%$ of OCRs are longer than 1 hour when $\rho = 2$ and $> 80\%$ of all OCRs exceed 3 hours when $\rho = 10$.

The Internet does, however, dynamically change thus new measurements are necessary when the TCP throughput has significantly changed. The Network Weather Service [33] periodically probes the network to resample the

TCP throughput. Instead, our system dynamically resamples the path at each OCR [20]. Dynamic monitoring is beyond the scope of this paper and is addressed in our other work [20].

We also assume that all of the parallel TCP flows see the same loss rate and have the same RTT , although both are functions of n and m . These two assumptions have been independently verified [27], as discussed in Section 2. We denote with p_n the loss rate after adding n parallel TCP connections, and with RTT_n the round trip time at this point.

Along different paths, the value of MSS can vary ranging from the default 536 bytes to much larger values (for example to support 9000 byte Ethernet jumbo frames on LANs). Our prediction model does not depend on the a priori knowledge of MSS . We do assume, however, that this value does not change after connection establishment. This is a valid assumption as both sides with either use path MTU discovery at connection establishment time [23] or use the default 576 byte path MTU.

Based on Equation 1 and the assumptions discussed above, we developed the following parallel TCP throughput model that essentially sums n TCP flows:

$$BW_n = \frac{MSS}{RTT_n} \frac{n}{\sqrt{p_n}} \frac{c_1}{\sqrt{\frac{2b}{3}}} \quad (3)$$

The TCP flows share the same RTT and loss rate and thus the same throughput. Both p_n and RTT_n are actually functions of n and m . Given that we assume m is stable during a period of time, we treat them as functions of n alone. c_1 is a constant in the range $(0, 1]$ that we use to represent the effects of TCP timeouts. In the following, we assume that c_1 is stable for a path over at least short periods, so that our model is equivalent to Padhye’s model with timeout considerations [26]. This assumption is firmly supported by the plethora of research on the statistical stability of TCP throughput as discussed above. Note that c_1 will be canceled in the following derivations, therefore our model doesn’t require the knowledge of c_1 .

If we had a model that could compute the relationship between p_n , RTT_n and the parallelism level n based on a small set of measurements, we could then use Equation 3 to predict the throughput for any parallelism level. This is in essence what we do. We developed several parametric models for this relationship based on measurements.

Morris [24] and Qiu, et al [27, 28] independently found that the loss rate is proportional to the square of the total number of TCP connections on the bottleneck link, namely $(m + n)^2$. Through wide area experiments, Hacker, et al [12, 13] showed that RTT on a given path is stable and can be treated as constant. Similarly, we also assume that RTT is a constant during a short period of time. There-

fore we have

$$p_n \times RTT_n^2 = a \times (m + n)^2 + b_1 \quad (4)$$

where b_1 is a constant. Given that m is also a constant, Equation 4 is equivalent to a full order 2 polynomial:

$$p_n \times RTT_n^2 = a \times n^2 + b_2 \times n + c_2 \quad (5)$$

where $b_2 = 2am$ and $c_2 = am^2 + b_1$. To use Equation 5, we need to send three probes at different parallelism levels to determine the value of a , b_2 and c_2 . Clearly, there is a trade-off between the sophistication of the model and the number of measurements needed to fit it. Recognizing this trade-off, we simplified the full order 2 polynomial to a partial order 2 polynomial as shown in Equation 6. This model requires only two probes to determine the parameters a and b .

$$p_n \times RTT_n^2 = a \times n^2 + b \quad (6)$$

Here a and b are parameters to be fit based on measurements. We could further simplify the partial order 2 model to a linear model that also requires two probes.

$$p_n \times RTT_n^2 = a \times n + b \quad (7)$$

We measured the performance of these three alternatives in a wide-area testbed [3], and found that

1. Equations 5 and 6 are better models than Equation 7.
2. The full order two polynomial model (Equation 5) is not significantly better than the partial order 2 polynomial (Equation 6) and can occasionally be worse due to its sensitivity to sampling errors caused by small network fluctuations. Another problem with the full order two polynomial model is that it is sensitive to the choice of probe parallelism.
3. The full order 2 model requires three probes instead of the two needed for the linear and partial polynomial models.

As a result, we use Equation 6 for our system and the discussion in the rest of the paper, unless otherwise noted.

In order to use the model in practice, we have to actively probe a path at two different parallelism levels. The procedure is derived as follows.

We denote $\frac{c_1}{\sqrt{\frac{2b}{3}}}$ in Equation 3 as C . Note that C and MSS are all constants under our assumptions. We define a new variable p'_n :

$$p'_n = p_n \frac{RTT_n^2}{C^2 MSS^2} = a'n^2 + b' \quad (8)$$

Combining Equations 3 and 8, we obtain:

$$BW_n = \frac{n}{\sqrt{p'_n}} \quad (9)$$

Based on Equation 9, we could use the TCP throughput at two different parallelism levels to predict the TCP

throughput at other levels. Let n_1 and n_2 be the two parallelism levels that are probed:

$$BW_{n_1} = \frac{n_1}{\sqrt{p'_{n_1}}} = \frac{n_1}{\sqrt{a'n_1^2 + b'}} \quad (10)$$

and

$$BW_{n_2} = \frac{n_2}{\sqrt{p'_{n_2}}} = \frac{n_2}{\sqrt{a'n_2^2 + b'}} \quad (11)$$

From which we can determine:

$$a' = \frac{\frac{n_2^2}{BW_{n_2}^2} - \frac{n_1^2}{BW_{n_1}^2}}{n_2^2 - n_1^2} \quad (12)$$

and

$$b' = \frac{n_1^2}{BW_{n_1}^2} - a'n_1^2 \quad (13)$$

By substituting a' and b' in Equation 8 with the expressions in Equations 12 and 13, we can now predict the TCP throughput for other levels of parallelism using Equation 9.

Notice how our prediction requires only *two* TCP throughput probes, one for each of the two different parallelism levels (n_1 and n_2). Both the probing and the calculation process are simple and incur little overhead, the majority being the communication cost of the two probes.

4.2. Evaluation

We evaluated our model through online experimentation on PlanetLab [3], a planetary-scale testbed. We randomly choose 41 distinct end-to-end paths with end nodes located in North America, Asia, Europe and Australia. For each path, we conduct 10 rounds of experiments using Iperf [1] to obtain our measurements. A round of experiment starts with two probes for prediction purposes, immediately followed by parallel TCP transfers with up to 30 parallel TCP flows.

We adopt the *mean relative error* as our performance metric. Relative error is defined as:

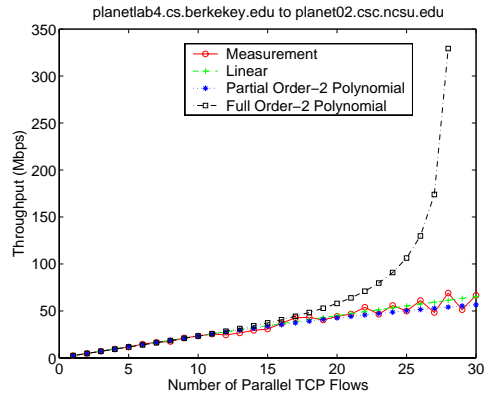

$$relative\ error = \frac{prediction - measurement}{measurement} \quad (14)$$

Mean relative error on a path is the average of all the relative prediction errors on the path. Mean relative error for a given number of parallel TCP flows is the average of the relative prediction errors of all the experiments for that number of parallel TCP flows.

Figure 3 shows two examples of prediction using our model. The graphs show the actual and predicted throughput (based on measurements at $n_1 = 1$ and $n_2 = 10$). It can be seen that, for Example 1, predictions made based on

(a) Example 1: from nbgisp.com to ucsb.edu

(b) Example 2: from berkeley.edu to ncsu.edu

Figure 3. Throughput prediction examples.

the partial order 2 and full order 2 polynomials are virtually identical and have similar accuracy, while the prediction curve derived using the linear model deviates significantly from the measurement curve. In our second example, the prediction made using the partial order 2 polynomial and the linear model are virtually identical and equally accurate. The prediction curve generated by the full order 2 polynomial, however, deviates significantly from the measurement curve.

Figure 4 shows the performance of our parallel TCP throughput predictor using two probes at parallelism levels $n_1 = 1$ and $n_2 = 10$ for all of the PlanetLab pairs. Only the partial order 2 polynomial model is used here. Both the mean and standard deviation of the relative errors (across different parallelism levels) is shown, with the graph ordered by the standard deviation. The results are quite encouraging: in most cases, our predictions have a small mean and standard deviation of relative prediction errors.

Our predictor is relatively insensitive to the particular level of parallelism for the probes. Figure 5 shows the mean relative error for our predictor using (1, 8), (1, 10) and (1, 15) parallel probes. We can see that we obtain sim-

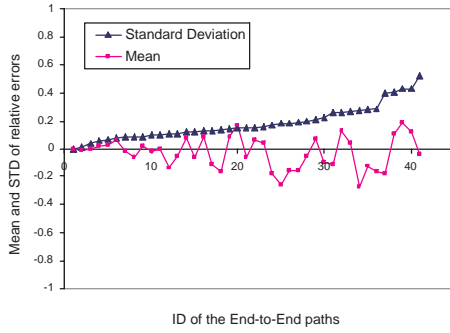

Figure 4. Prediction error statistics. Paths ID are ordered by the standard deviation.

Figure 5. Prediction sensitivity to the selection of probes.

ilar performance in all cases. Of course, it is important not to use parallelism levels that are too close together (such as (1, 2)), as such probes are very sensitive to small fluctuations in the network or the existing cross traffic.

As it can be seen from Figure 6, the mean relative error for a given number of parallel TCP flows is not related to the number of parallel TCP flows. The figure, a scatter plot of the mean relative error (across all 41 paths) versus the number of parallel TCP flows, shows no clear trend. The correlation coefficient R between the mean relative prediction error and the number of parallel TCP flows is < 0.1 .

Our experimental results have shown how, using the model derived in this section, one can effectively predict the throughput of parallel TCP for a wide range of parallelism relying only on two active probes at different levels of parallelism. In the following we try to estimate the effect of parallel TCP in the existing cross traffic for a given level of parallelism, the last “piece” necessary to make the `TameParallelTCP()` call possible.

Figure 6. Relative prediction error for parallel TCP throughput as a function of number of parallel TCP flows.

5. Taming parallel TCP

There are a number of considerable challenges when trying to estimate the effect on cross traffic with an online system running on the end points:

1. The available bandwidth on the bottleneck link(s) is unknown.
2. The number of cross traffic flows and their loss rates and bandwidths on the bottleneck link(s) (the offered load) are unknown.
3. Making use of an additional network measurement tool (such as Pathload [16]) to determine the current load on the path is problematic since it can take a long time to converge. In addition, the measurement accuracy cannot be guaranteed. One would like to avoid any additional overhead beyond the required two active probes necessary to predict the throughput of parallel TCP flows.

In what follows, we make simplifying assumptions about the cross traffic’s view of the shared links on the path in order to provide an estimate of impact on the cross traffic from the same two probes from which we derived the throughput curve in the previous section.

5.1. Algorithm

We assume that all TCP connections, including our parallel TCP flows and the cross traffic, share the same loss rate on a bottleneck link. This assumption is valid as long as one of the two following conditions can be satisfied:

1. The cross traffic has an RTT similar to our parallel TCP flows. In that case, all connections are very likely to have their congestion window synchronized, and thus share the same loss rate. This fact has been independently verified by other research groups [29, 27, 28].
2. The router on the bottleneck link is using Random Early Detection (RED) [9] as its queue management policy, something that is becoming increasingly common. Research has demonstrated that with RED, different flows roughly experience the same loss rate (the RED rate, which depends on the queue occupancy) under steady state [9, 28].

Our approach to determining the effect of parallel TCP on cross traffic is based on our algorithm to estimate the parallel TCP throughput (Section 4). The key idea is to estimate $p_n \times RTT_n^2$ as a function of the number of parallel TCP flows. Based on the assumption that cross traffic shares the same loss rate as parallel TCP flows, we can then use the simple TCP throughput model (Equation 1) to estimate the relative change to the cross traffic throughput.

Recall in Section 4 that we model $p_n \times RTT_n^2$ with a partial order 2 polynomial function $a \times n^2 + b$ (Equation 6). After obtaining the two necessary measurements, we can calculate the value of a and b and are now able to estimate the loss rate as a function of the number of parallel TCP flows.

Relying on our assumptions, we have also obtained the loss rate of the cross traffic as a function of the number of parallel TCP flows n given there are m cross traffic flows (recall that m is relatively stable, see Section 4).

Thus, based on Equation 1, we can now estimate the relative change on each of the individual TCP throughputs without knowing m using the following equation:

$$relc = \frac{\frac{MSS \times C}{RTT_{n1} \times \sqrt{p_{n1}}} - \frac{MSS \times C}{RTT_{n2} \times \sqrt{p_{n2}}}}{\frac{MSS \times C}{RTT_{n1} \times \sqrt{p_{n1}}}} \quad (15)$$

$$= 1 - \sqrt{\frac{p_{n1}}{p_{n2}}} \quad (16)$$

$$= 1 - \sqrt{\frac{a \times n_1^2 + b}{a \times n_2^2 + b}} \quad (17)$$

Here, $relc$ is the relative throughput change for each flow. Equation 16 shows that all the flows share the same relative throughput change. MSS and C are constants as described in Section 4, and RTT_n is stable as was shown by Hacker, et al [12]. $\sqrt{\frac{p_{n1}}{p_{n2}}}$ can be estimated using Equation 6. Both a and b can be obtained with two probes as we discussed in Section 4. Note that n_1 and n_2 can be any parallelism levels. In practice, however, we are most interested in estimating the relative throughput change after adding in n_2 parallel TCP flows in comparison with adding in only one TCP flow, therefore n_1 equals 1 in this case.

In practice, we add another constraint to the `TameParallelTCP()` function to avoid the potential “diminishing returns” problem where more parallel TCP flows bring only marginal benefits. With the `TameParallelTCP()` function, we can estimate the aggregate throughput at any parallelism level. We then check to ensure that the performance gain is over an administrator-determined threshold after adding in an additional TCP flow. If the performance gain is below the threshold, we do not add more flows even when the impact on cross traffic is within the user’s limit. This is important because we can avoid the system overhead and network overhead by avoiding unnecessary TCP flows.

(a) Scenario 4 with 5 cross traffic

(b) Scenario 6 with 15 cross traffic

Figure 7. Cross traffic estimation examples.

5.2. Evaluation

We have done a thorough ns2-based evaluation of our cross traffic estimator. The simulator allows us to analyze our estimator by controlling settings including bottleneck bandwidth and cross traffic characteristics.

Our simulation configuration was introduced in Section 3. We consider the same set of the scenarios presented there. As in Section 3, we employ Qiu et al’s [27] simulation topology (Figure 1).

Figure 7 shows two examples, for Scenarios 4 and 6, of the performance of our estimator. In these cases we can accurately predict the impact on cross traffic as a function of the parallelism level using only two probes, the same probes we use to predict the throughput of the parallel flows as a function of parallelism level.

We summarize our prediction results as a CDF of the relative error in predicting the impact on cross traffic across all of our scenarios in Figure 8. We can see that 90% of predictions have relative prediction error less than 0.25. The cross traffic estimator is slightly biased. It conservatively predicts a greater impact on the cross traffic on average.

To further evaluate our cross traffic estimation algorithm, we designed a more complex topology with two groups of cross traffic. The topology and the simulation configuration is shown in Figure 9. Each simulation is 100 seconds long with cross traffic starting randomly between 0 and 8 seconds and all the parallel TCP flows starting at 10 seconds.

Figure 8. Cumulative distribution function of relative prediction error for cross traffic estimation for all the simulations with 6 scenarios as described in Figure 2.

Figure 9. More complex topology for further evaluation of cross traffic estimation.

L1 and L4 have latency 3 ms, L2 and L5 have latency 6 ms, L6 and L7 have latency 10 ms. L3 has latency 50ms and bottleneck bandwidth 1000 Mbit/s. N3 is using the RED queue management policy. Parallel TCP flows go from N2 to N6. Cross traffic group 1 goes from N7 to N6. Cross traffic group 2 goes from N1 to N5. We applied our estimation algorithm to these scenarios, resulting in Figure 10.

We also tested the cross traffic estimator for scenarios in which different TCP flows have different RTTs, and where RED is not used on the routers. Our estimator shows the right trend of the cross traffic throughput change, although accurate prediction cannot be guaranteed as flows with longer RTT tend to have higher loss rate than parallel TCP flows and vice versa. In essence, in situations in which cross traffic RTT and loss rate is unknown, our estimator is less accurate.

5.3. Outcome

We have demonstrated the feasibility of predicting the impact on cross traffic of a parallel TCP transfer as a func-

Figure 10. Estimation results with 14 TCP flows in cross traffic group 1 (g1) and 14 TCP flows in cross traffic group 2 (g2).

tion of the degree of parallelism. Under the assumption that all flows share the same loss rate, we can accurately predict the relative impact using the same two measurement probes used to predict the throughput of the parallel TCP transfer as a function of the degree of parallelism.

Combining these two predictions, we can implement the `TameParallelTCP()` API call:

1. Execute two probes at different parallelism levels.
2. Using the probe results, estimate the parallel TCP throughput as a function of the number of parallel TCP flows n using the techniques of the previous section.
3. Using the probe results, estimate the relative impact on cross traffic as a function of n using the techniques of this section.
4. Conduct a binary search on the cross traffic impact function, looking for the degree of parallelism, l , that has the largest impact less than that permitted in the API call.
5. Return l , and the impact and throughput predictions at parallelism l .

The cost of this implementation is dominated by executing the two probes.

6. Conclusions and future work

We have shown how to predict both parallel TCP throughput and its impact on cross traffic as a function of the degree of parallelism using only two probes at different parallelism levels. Both predictions are monotonically changing with parallelism levels. Hence, the `TameParallelTCP()` function can be implemented using a simple binary search. To the best of our knowledge, our work is the first to provide a practical parallel TCP throughput prediction tool and to estimate the impact on the cross traffic.

We have made a few simplifying assumptions about the cross traffic in order to predict impact on it while having no knowledge of the actual cross traffic. While these assumptions are reasonable in many cases, we are now working on how to relax them. An implementation of a version of our `TameParallelTCP()` function is available from <http://plab.cs.northwestern.edu/Clairvoyance/Tame.html>.

Although the Internet paths show statistical stability, the transient stability won't hold over the long term. Either periodic resampling as in NWS [33] or the dynamic sampling rate adjustment algorithm from our other work [20] can be applied for the long term monitoring.
